Isolating discrete populations of germ cells from the mouse testis is challenging, because the adult testis contains germ cells at every step of spermatogenesis, in addition to somatic cells. We present a novel method for isolating precise, high-purity populations of male germ cells. We first synchronize germ cell development in vivo by manipulating retinoic acid metabolism, and perform histological staging to verify synchronization. We use fluorescence-activated cell sorting to separate the synchronized differentiating germ cells from contaminating somatic cells and undifferentiated spermatogonia. We achieve ~90% purity at each step of development from undifferentiated spermatogonia through late meiotic prophase. Utilizing this “3S” method (synchronize, stage, and sort), we can separate germ cell types that were previously challenging or impossible to distinguish, with sufficient yield for epigenetic and biochemical studies. 3S expands the toolkit of germ cell sorting methods, and should facilitate detailed characterization of molecular and biochemical changes that occur during the mitotic and meiotic phases of spermatogenesis.

1. Introduction

Much is still unknown about the molecular and biological changes that occur during mammalian spermatogenesis—the transformation of spermatogonial stem cells into highly specialized spermatozoa. During this process, germ cells proliferate mitotically and extinguish pluripotency markers, and then divide meiotically to produce haploid gametes, which undergo further differentiation to become mature spermatozoa. To fully understand the molecular and biochemical changes underlying spermatogenesis would require isolating each step along this developmental progression—an extraordinarily difficult effort because the adult testis contains both somatic cells and millions of asynchronously developing germ cells. We present here a novel method, “3S” (synchronize, stage, and sort), which isolates precise populations of mitotic and meiotic germ cells for study, circumventing the cellular complexity of the testis. 3S combines two approaches to germ cell isolation—in vivo simplification of the cellular composition of the testis, followed by ex vivo cell sorting.

Previous attempts to isolate specific germ cell populations have largely relied on cell sorting, using the unperturbed wild-type testis as starting material. While new molecular markers of germ cell development are continually being discovered, thus far such molecular markers have mostly been used to isolate certain subtypes of spermatogonia (Chan et al., 2014; de Rooij, 2017; Lord and Oatley, 2017; Oatley and Brinster, 2008; Shinohara et al., 2000). To isolate other germ cell populations, investigators have instead relied on more general cell properties. Sedimentation-based approaches, including unit gravity sedimentation and centrifugal elutriation, separate germ cells based on size and density (Bellvé, 1993; Grabske et al., 1975). DNA staining/FACS (fluorescence-activated cell sorting) uses a dye such as Hoechst 33342 to separate germ cells based on DNA content and light scattering properties (Bastos et al., 2005; Gaysinskaya et al., 2014). Both of these approaches can, with high accuracy, separate mitotic, meiotic, and post-meiotic germ cells from one another and from the somatic cells of the testis. Each of these approaches has its own unique strengths: for instance, sedimentation-based approaches are particularly well-suited to isolating post-meiotic cell types, while DNA-staining/FACS excels at isolating meiotic prophase cells from the adult testis. However, both approaches have limited resolution, particularly during the mitotic and early meiotic phases of spermatogenesis: they frequently combine multiple closely related steps of germ cell development into a single sorted population.

We therefore saw the need for an additional germ cell sorting method, designed to isolate mitotic and meiotic germ cell subpopula-
A. Germ cell types that can be isolated with “3S”

fig. 1. overview of “3s” (synchronize, sort, and stage). (a) schematic of germ cell development in the testis of an unperturbed male mouse, showing germ cell populations that can be isolated with “3s.” in the neonatal mouse, the only germ cells present are undifferentiated spermatogonia: these encompass the spermatogonial stem cells, which persist throughout the animals lifetime. in a retinoic acid (ra)-dependent fashion, cohorts of these undifferentiated spermatogonia then differentiate to become mitotic differentiating spermatogonia (ai, a2, a3, a4, intermediate, and b). germ cells next initiate meiosis and undergo pre-meiotic dna replication as preleptotene spermatocytes, and then go through meiotic prophase (leptotene, zygotene, pachytene and diplotene spermatocytes) and two reductive divisions. finally, germ cells go through post-meiotic development (round and elongating spermatids). populations from undifferentiated spermatogonia through mid-pachytene (black bar) can be easily isolated with 3s using the mvh-cre/tdtomato germ cell lineage tracing system (fig. 6). later steps of germ cell development (gray bar) are more difficult to isolate by sorting, due to differentiation of subsequent cohorts of undifferentiated spermatogonia and to diminished fluorescence from the mvh-cre/tdtomato lineage tracing system. (b) the “3s” protocol. b-1: description of the synchronization procedure. win18,446 (gray) inhibits ra synthesis. the provided timeline for synchronous development after ra injection is for a typical c57bl/6 mouse. b-2: description of the staging procedure. a small portion of the synchronized testis is embedded in paraﬃn, sectioned, and examined with a light microscope, to conﬁrm that germ cells have reached the desired step of development, as described in (ahmed and de Rooij, 2009). staging veriﬁes the identity of the sorted germ cells. b-3: description of the sorting procedure (performed in parallel with staging). schematic shows digestion of the testis into a single-cell suspension, followed by faces (ﬂuorescence-activated cell sorting). schematic for faces shows identiﬁcation of three cell populations (leptotene spermatocytes, spermatagonium, and somatic cells) by a combination of cell size, as approximated by light scatter, and tdTomato ﬂuorescence intensity. based on this identiﬁcation, leptotene spermatocytes are selectively sorted. for a description of the mvh-cre/tdtomato germ cell lineage tracing system, see Fig. 6.

B. the “3s” protocol

example: isolating leptotene spermatocytes (early meiotic prophase)

1) synchronize (~2 days)

Begin with 2-day-old male mouse → Inject win18,446 daily for 7 days to inhibit spermatogenesis

2) stage (~2 days)

Section testes onto microscope slides; verify by morphological appearance that germ cells have reached desired stage of development

3) sort (~2 hours, in parallel with staging)

Digest testes to get a single-cell suspension → Identify desired germ cells (using size and/or a marker system) and sort by faces

Output: live germ cell population with ~90% purity and veriﬁed identity
tions with high resolution. We were motivated by two cases in particular where greater resolution would be helpful. First, the mitotic phase encompasses seven histologically distinct steps of germ cell development (A_{undiv}/A_1/A_2/A_3/A_4/Intermediate/B spermatogonia, Fig. 1A), which DNA staining/FACS (Gaysinskaya et al., 2014) cannot separate, and which unit gravity sedimentation can separate into only two populations. During this mitotic phase, germ cells undergo important functional changes, losing expression of pluripotency markers and acquiring competence to enter meiosis (Buas et al., 2004; Endo et al., 2015; Shinohara et al., 2000). However, the transcriptional, post-transcriptional, and epigenetic changes that underlie these functional changes are still poorly understood (de Rooij and Griswold, 2012; Zhang et al., 2014). Similarly, the first two steps of meiotic prophase, leptotene and zygotene, are histologically distinct and encompass distinct chromosomal events, with programmed double-strand breaks occurring during leptotene, and synopsis of homologous chromosomes beginning at zygotene (Fig. 1A). These populations cannot be separated with sedimentation-based approaches, and are difficult to separate with DNA staining/FACS approaches (Bellvé, 1993; Gaysinskaya et al., 2014). If leptotene and zygotene germ cells could be effectively separated, their RNA and protein content and chromatin state could be systematically characterized (da Cruz et al., 2016; Gaysinskaya et al., 2014).

When separating germ cell subpopulations, a common approach to avoid the complexity of the adult testis is to use the juvenile testis, which displays more circumscribed cellular heterogeneity. Since spermatogenesis begins before birth, one can isolate testes that are enriched for mitotic or meiotic germ cells by timed collection (Bellvé, 1993; Margolin et al., 2014). However, asynchrony is present from the very beginning of spermatogenesis in neonatal males, so sorting precise germ cell subpopulations from the juvenile testis is still challenging (Nehel et al., 1961; Snyder et al., 2010). An alternative approach is to induce synchronization of germ cell development by manipulating retinoic acid (RA) levels in vivo. In the absence of RA, germ cells arrest as “undifferentiated spermatogonia,” a population which encompasses the spermatogonial stem cells. A single pulse of RA can then induce spermatogonial differentiation throughout the entire testis. Spermatogenesis proceeds synchronously for months thereafter.

Synchronization was first achieved by withholding and then restoring vitamin A, the metabolic precursor of RA, in the diets of adult mice or rats (Morales and Griswold, 1987; van Pelt and de Rooij, 1990). However, synchronization by vitamin A deprivation is not practical to apply on a large scale: it is time-consuming, requiring approximately five months of dietary manipulation and more than two months of animal weighing, and it is quite detrimental to animal health. More recently, Hogarth et al. (2013) developed a practical synchronization method using the compound WIN18,446 [also known as N,N’-1,8-Octanediylbis(2,2-dichloroacetamide)], which inhibits RA synthesis. In these studies, Hogarth et al. administered WIN18,446 to juvenile mice for 7 days (d), followed by a single dose of RA; they achieved synchronization with only 8 d of animal manipulation. Following either of these synchronization protocols, the cellular composition of the testis is dramatically simplified: for instance, a synchronized testis might contain germ cells in leptotene, but not germ cells in any other phase of meiosis (Fig. 1B). Synchronization does not seem to interfere with normal germ cell biology and function. After synchronization, spermatogenesis proceeds with normal timing; germ cells have normal microscopic appearance; and animals are fully fertile, producing litters of normal size (Hogarth et al., 2013; Huang and Hembree, 1979; Morales and Griswold, 1987; van Pelt and de Rooij, 1990).

Our 3S (synchronize, stage, and sort) method combines these two complementary approaches: in vivo simplification of the cellular composition of the testis, and ex vivo cell sorting. First, we have developed a refined WIN18,446/RA synchronization protocol. This protocol yields predictable timing of germ cell development, which allows us to enrich for precise steps of development simply by timed collection of the testis (Fig. 1B-1). Second, we have developed FACS protocols to efficiently sort the synchronized germ cells from contaminating somatic and undifferentiated spermatogonial populations (Fig. 1B-3). Histological staging of a reserved portion of the synchronized testis allows us to verify that synchronization was successful and that we have isolated the desired cell population (Fig. 1B-2). With 3S, we can achieve ~90% purity of germ cell subpopulations from the undifferentiated spermatogonia through late meiotic prophase.

2. Results

We present in turn detailed protocols and typical results for synchronization, staging, and sorting of male germ cells.

2.1. Step 1: Synchronization

As shown in Fig. 1B-1, we first synchronize germ cell development in vivo, such that, at the time of collection, the testis is highly enriched for the germ cell population of interest. Synchronization requires a series of eight daily injections: seven injections of WIN18,446 to hold spermatogenesis in an undifferentiated state, followed by a single RA injection to synchronously induce spermatogonial differentiation. After these injections, the synchronized cohort of germ cells follows the developmental progression shown in Fig. 1A. They first go through six mitotic divisions, becoming in turn A_1, A_2, A_3, A_4, Intermediate, and B spermatogonia. After the sixth mitotic division, the germ cells become preleptotene spermatocytes, during which stage they initiate meiosis and undergo pre-meiotic DNA replication. They then enter meiotic

![Fig. 2. An example of synchronization. Testis sections, stained for SYCP3 (green) and γH2AX (red) and counterstained with DAPI (blue). Cells with high levels of SYCP3 and low/punctate γH2AX are in late leptotene, approaching zygotene. Scale bars, 50 μm. (A) Control, unsynchronized pubertal testis, p10. At this time-point, the unsynchronized testis is relatively enriched for leptotene spermatocytes. Nevertheless, the staining patterns of individual tubules are highly heterogeneous. Most tubules have little or no SYCP3 expression, indicating that they do not contain meiotic spermatocytes. (B) Synchronized testis, 9 d after RA restoration. All tubules are dominated by cells with high SYCP3/low γH2AX, indicative of synchronization at the end of leptotene. Fig. 3. Typical time-course of synchronization. Left column: Days after RA restoration, and most advanced (and most prevalent) steps of germ cell development observed. A minimum of 100 tubules was scored for each sample. Middle column: histology. Section in (C) is stained for STRA8 (brown) and counter-stained with hematoxylin (blue); all other sections are stained with hematoxylin only. Scale bars, 100 µm. Right column: Steps of germ cell development present in each tubule. Grayscale version of image in middle column, with all germ cells in the section marked with colored dots as indicated. All unmarked cells are somatic. For each time-point (A–F), the cells in one example tubule (indicated by dashed black outline) are counted. Germ cells were identified by hematoxylin staining patterns as described in (Ahmed and de Rooij, 2009); STRA8 staining was used to distinguish between STRA8-positive and -negative preleptotene spermatocytes. (Note that, because STRA8 is also expressed in some spermatogonia (Endo et al., 2015), preleptotene spermatocytes cannot be identified by STRA8 staining alone.) Undiff.: undifferentiated. Diff.: differentiating. (A) Just before RA restoration. 100% of tubules contain undifferentiated spermatogonia as their only germ cell population. Thus, undifferentiated spermatogonia and somatic cells are the only cell types in the testis; most cells in the testis at this time-point are somatic. (B) 5.75 d after RA restoration. 99% of tubules contain type-B (late differentiating) spermatogonia as their developmentally most advanced (and most prevalent) germ cell population. Tubules also contain somatic cells and a few undifferentiated spermatogonia. These three cell types make up the great bulk of this testis. The 1% of tubules without type-B spermatogonia, which arise due to imperfect synchronization, contribute a few Intermediate spermatogonia. (C, D, E, and F): 7, 8, 10, and 12 d after RA restoration. 91%, 97%, 94%, and 99% of tubules contain, respectively, STRA8-positive preleptotene, leptotene, zygotene, or pachytene spermatocytes as their developmentally most advanced germ cell populations. Tubules also contain somatic cells and a few spermatogonia. The spermatogonia are a mixture of undifferentiated and differentiating spermatogonia, with the undifferentiated spermatogonia encompassing the spermatogonial stem cells, and the differentiating spermatogonia representing a second synchronous generation of germ cells, developing behind the meiotic cohort.

prophase, becoming in turn leptotene, zygotene, pachytene, diplotene, and secondary (dividing) spermatocytes, before undergoing postmeiotic differentiation as round and elongating spermatids (Russell et al., 1990). Based on this developmental progression, we collect tissue at the time-point dictated by the cell population of interest (Figs. 2–4). Note that we are generally collecting testes from pubertal animals (9 days after birth or older). This use of pubertal tissue is common to many germ cell enrichment techniques (Bellvé, 1993; Nebel et al.,...
Mice, 2 days (d) after birth (p2): Any strain of mice can be used, but 2.1.1. Materials components. First, our mice are heterozygous for genetically encoded lineage tracing system, which consists of two STOP-loxP-tdTomato construct in the

We genotype mice for Mvh-Cre and tdTomato by PCR, as described in a Cre-mOrange fusion protein, driven by the endogenous system; the mOrange

1961), but investigators should nevertheless be aware of possible subtle differences from adult germ cells.

We now describe the protocol for synchronization in detail.

2.1.2. Procedure

1) Begin with a single dam and her litter of pups, at p2. Before beginning dosing, we recommend removing any co-housed adult mice; this improves pup health and survival. If the litter is especially large (> 6 pups for C57BL/6), we recommend euthanizing some of the female pups to reduce litter size. Also check that the dam is nesting well and that pups are healthy and of normal weight (for C57BL/6 mice, > 1.5 g at p2). Developmental timing after synchronization is less consistent in low-weight pups.

2) Prepare WIN18,446 suspension fresh each day, directly before injection. For 1 ml, dissolve 5 mg of WIN18,446 in 25 μl of DMSO. Add 475 μl of sterile PBS and immediately shake to mix, generating a cloudy suspension. Always add PBS to WIN18,446/DMSO, rather than the reverse, to avoid precipitation of the WIN18,446.

3) Inject 10 μl per g body weight subcutaneously (over the shoulders) into male mice, once per day for 7 d. To reduce the risk of clogging, shake the WIN18,446 suspension well before filling the syringe, and load only ~300 μl at a time. The first injection should be performed around noon; subsequent injections can be given at any time of day. If schedule requires, a single day’s injection can be skipped, as long as injections are no more than 48 h apart. Note that pups sometimes develop a hairless patch on their neck from repeated injections; this is not harmful.

4) At p9 (day 8 of the protocol), check animal weight. If the animal is of healthy weight (> 5 g in C57BL/6), it is ready for RA injection or tissue collection, as described below. In these normal-weight animals, germ cell development is expected to proceed with typical timing (Fig. 4A). If an animal is somewhat smaller (< 4 g with an unhealthy appearance), it is best to euthanize them. If used, they should be carefully monitored, and germ cell development may be significantly slower than usual (Fig. 4B).

5) If the desired germ cell population consists of undifferentiated spermatogonia, euthanize the animal, dissect the testes and proceed to sorting and staging. Otherwise, prepare RA suspension for injection: first, make 100 mM RA stock (e.g. 50 mg RA + 1.664 ml DMSO). Then, mix 1.917 ml of water with 83 μl of the RA stock. The first injection should be performed

WIN18,446, often sold under the name N,N′-Octamethylenebis(2,2-dichloroacetamide) or Fertilysin™. We source our WIN18,446 from MP Biomedicals (catalog number 02158050) or from Santa Cruz Biotechnology (catalog number sc-295819).

Carriers for WIN18,446 and RA suspensions: DMSO, PBS, and water. These should be sterile and of pharmaceutical grade.

For injections: 1 ml syringes; 26-gauge needles, 3/8 in. or less in length. It is important to use a short needle of adequate diameter to reduce the risk that the WIN18,446 or RA suspension will clog the needle.

6) (Optional, but recommended) After RA injection, remove or euthanize any co-housed un-injected pups. RA-injected pups recover better if they do not need to compete with un-injected animals. Monitor pups after injection, and choose the collection time-point based on the desired germ cell population. Developmental timing will have to be determined anew for each strain, and may vary somewhat from investigator to investigator even when working with the same strain. As a starting reference, our observed timings in normal-weight C57BL/6 animals are shown in Fig. 3 and Fig. 4A. As noted above, the timeline of germ cell development is prolonged in underweight animals. If a pup appears unhealthy, or is not gaining weight appropriately, do not expect normal germ cell developmental timing (Fig. 4B). It may be best to euthanize the animal. At the time of collection, euthanize the animal, dissect out the testes, and proceed to sorting and staging. Note that, if collecting within 1–2 days of RA injection, RA levels in the testis may still be elevated. Since the biological half-life of RA is less than 1 h (Hogarth et al., 2015; Le Doze et al., 2000), we do not expect this to be a concern at later time-points.

Fig. 2 shows typical results of synchronization. In this experiment, development has been allowed to proceed for 9 d after the RA injection, in order to collect late leptotene spermatocytes. Sections from an unsynchronized control and a synchronized testis are stained for two
meiotic markers: γH2AX, which marks double-strand breaks (Rogakou et al., 1998), and SYCP3, a component of the synaptonemal complex (Yuan et al., 2000). In the unsynchronized control, the tubules display heterogeneous staining patterns: a few tubules contain late leptotene spermatocytes, but most contain only germ cells at earlier steps of mitotic and meiotic development. In contrast, in the synchronized testis, each tubule displays the same staining pattern, indicating that late leptotene spermatocytes are the developmentally most advanced (and most prevalent) germ cells in > 95% of tubules.

We next investigated whether WIN18,446/RA synchronization perturbs testicular gene expression. To do this, we analyzed publicly available microarray datasets from WIN18,446/RA synchronized testes (Evans et al., 2014) and unsynchronized/untreated testes (Shima et al., 2004), comparing gene expression patterns 0–8 days after RA restoration to gene expression patterns in the unsynchronized juvenile testes at matched time-points (Supplemental Fig. 1). Our analysis shows that gene expression patterns in the synchronized dataset are more concordant with one or more of the unsynchronized datasets than the unsynchronized datasets are with each other. We therefore conclude that differences in expression patterns between unsynchronized and synchronized testes are below the level of technical noise in this dataset comparison, and thus are likely quite subtle. This result is in line with previous literature showing the normalcy and fertility of the synchronized testes (Hogarth et al., 2013; Huang and Hembree, 1979; Morales and Griswold, 1987; van Pelt and de Rooij, 1990). As with all cell purification methods, we cannot rule out functional changes to germ cells as a result of synchronization (or subsequent sorting). However, the available evidence (the short biological half-life of RA, the fertility of RA-synchronized animals, and the apparently normal gene expression) strongly suggests that any such functional changes are subtle.

Figs. 3 and 4 show the enrichment of different germ cell populations at various time-points after RA restoration in C57BL/6 mice. Immediately prior to RA restoration (Fig. 3A), the only germ cells in the testis are undifferentiated spermatogonia (Fig. 1A). At 5.75 d after restoration, the testes are populated with late leptotene spermatocytes (Fig. 3B). As RA treatment continues, the number of late leptotene spermatocytes increases, and by 8 d, the testis is populated with late pachytene spermatocytes (Fig. 3C). These results are consistent with previous studies showing the normalcy and fertility of RA-synchronized animals.
RA restoration, the most advanced germ cells in each tubule are type B spermatogonia; the testis also contains some undifferentiated spermatogonia (Fig. 3B). At 7 d after RA restoration, the most advanced germ cells are preleptotene spermatocytes that are positive for the meiotic initiation factor STRA8 (Baltus et al., 2006; Mark et al., 2015) (Fig. 3C). At 8, 10, and 12 d after RA restoration, the most advanced germ cells are progressively further into meiotic prophase (Fig. 3D-F). We note that this timetable of germ cell development is more rapid than is usually observed in the adult, consistent with previous observations that pubertal spermatogenesis proceeds more rapidly than adult spermatogenesis (de Rooij and Russell, 2000; Kluin et al., 1982). From 7 d onward, a new generation of germ cells begins differentiating synchronously behind the meiotic cohort (Fig. 3 C-F) (Russell et al., 1990), increasing the total number of spermatogonia in the testis. In normal-weight animals, the timetable of synchronized germ cell development is quite consistent from animal to animal, and synchronization does not deteriorate significantly during these 12 d of development (Fig. 4A). We calculate that, throughout this period, germ cell development is synchronized to within a 24 h developmental window. This is a significant improvement over the unsynchronized juvenile testis, the most and least advanced members of the first cohort of differentiating germ cells are separated by more than 3 d of development (Nebel et al., 1961; Russell et al., 1990).

### 2.2. Step 2: Staging

To establish the timing of germ cell development after RA restoration, it is important to histologically examine (“stage”) a portion of one testis from each synchronized and staged animal. At least 50 randomly selected cells were assessed for each animal. Purities were assessed by immunostaining (Fig. 9). For the leptotene and zygotene sorts, STRA8-positive and STRA8-negative preleptotene spermatocytes were not distinguished. Purities are given rounded to the nearest 0.5%. Purities that could be obtained without the Mvh-Cre/tdTomato lineage tracing system were estimated based on the percentage of cells excluded by gating for tdTomato intensity in each sort (e.g. Figs. 5D, 7B, and 7E). These purities will likely be underestimates, as we assume that none of the excluded cells belong to the target populations. Prelep., Lep., Zyg., Pachy.: preleptotene, leptotene, zygotene, and pachytene spermatocytes. N.D.: not determined.

#### Table 1
**Purities of sorted cell populations.** For each target population (STRA8-positive preleptotene, leptotene, or zygotene spermatocytes), three sorts were performed, each from a single synchronized and staged animal. At least 50 randomly selected cells were assessed for each animal. Purities were assessed by immunostaining (Fig. 9). For the leptotene and zygotene sorts, STRA8-positive and STRA8-negative preleptotene spermatocytes were not distinguished. Purities are given rounded to the nearest 0.5%. Purities that could be obtained without the Mvh-Cre/tdTomato lineage tracing system were estimated based on the percentage of cells excluded by gating for tdTomato intensity in each sort (e.g. Figs. 5D, 7B, and 7E). These purities will likely be underestimates, as we assume that none of the excluded cells belong to the target populations. Prelep., Lep., Zyg., Pachy.: preleptotene, leptotene, zygotene, and pachytene spermatocytes. N.D.: not determined.

</table>
cells (or extracted RNA, protein, etc.) until staging is complete, whereupon we pool sorted cells from multiple animals and proceed with downstream studies.

The technique we use for preparing tissues is:

1) Cut one testis in half, using small dissection scissors to split the tunica albuginea. Fix the half testis and associated piece of tunica for 4 h in Bouin’s solution.

2) Embed tissue in paraffin, section (5 μm width), and stain with hematoxylin.

Then, for each tubule cross-section, determine its stage: that is, the most advanced (and most prevalent) step of germ cell development. Staging requires a light microscope with an oil objective and 100x magnification. Staging takes some effort to learn; two excellent references are Ahmed and de Rooij (2009) and Russell et al. (1990).

Some practical tips for learning to stage:

- By histology alone, leptotene is one of the easiest phases of germ cell development to identify; see the characteristic speckled hematoxylin staining in Fig. 3D.
- Preleptotene spermatocytes are also reasonably easy to identify by histology.
- Later phases of meiosis (zygotene, early/mid/late pachytene, diplote
tene) are more difficult to identify by histology, but their identity can be readily confirmed by meiotic spreads (de Boer et al., 2009; Peters et al., 1997).

Investigators can decide their own criteria for sample inclusion following staging. We include samples in which > 90% of tubules contain germ cells at the desired step in their development, and we discard sorted material from samples that do not meet these criteria.

After synchronization and staging, tests are already substantially enriched for the germ cell population of interest, though of course somatic cells and spermatogonia are still present (Fig. 3). These synchronized and staged samples (“2S”) can in some cases be used directly for downstream experiments, but in most cases investigators will want to proceed to sorting (Fig. 1B-3).

2.3. Step 3: Sorting

Sorting separates the desired germ cell population from contaminat

2.3.2. Procedure

1) Make fresh a collagenase solution (HBSS + 1 mg/ml collagenase + 1:1000 DNAse), and a collagenase/trypsin solution (HBSS + 1 mg/ml collagenase + 0.05% trypsin + 1:1000 DNAse). Warm both solutions to 35 °C.

2) Remove the tunica albuginea from the collected testes and place the testes in 1 ml of collagenase solution in a 1.7 ml microtube.

3) Shake the tube vigorously by hand until the tubules begin to separate from each other. Then, slowly, gently shake in a horizontal position for 7 min at 35 °C. (Shaking may be done manually or mechanically, and may be performed at room temperature rather than at 35 °C if necessary.) Halfway through this shaking period, gently pipette the tubules up and down with a 1 ml pipette tip to assist in the tubule dispersion. By the end of the 7 min period, most tubules should appear thin and dispersed, though a few clumps may remain.

4a) (Standard protocol.) Place the tube in a vertical position and leave undisturbed at room temperature for 2 min, to allow tubules to settle to the bottom. Remove and discard the supernatant (which contains unwanted somatic cells from the testicular interstitium), leaving enough liquid to cover the tubules generously. Add 1 ml of collagenase/trypsin solution.

4b) (Alternate protocol to minimize tissue loss, for small quantities of tissue such as testes collected at 0 d after RA injection.) Do not remove supernatant. Instead, after tubule dispersion, add trypsin stock solution directly to the tubule/collagenase mixture, to achieve a final concentration of 0.05% trypsin.

5) Gently shake in a horizontal position for 20 min at 35 °C. Every 5 min, gently pipette the tubules up and down to assist in digestion. After 10 min, add an additional 8 μl of 2.5% trypsin; if digestion solution is overly viscous, also add an additional 1 μl of DNAse I stock. At the end of this digestion period, the testis tubules should be reduced to a single-cell suspension.

6) Quench digestion with 400 μl of serum, mixing thoroughly by pipetting.

7) Wash, filter, and stain the testicular cells in preparation for sorting: spin down the cell suspension at room temperature for 5 min at 2000 g, remove the supernatant, and re-suspend in 500 μl of ice-cold HBSS, making sure to thoroughly break up the cell pellet by repeated pipetting. Keep the cells on ice until ready to sort.

8) Immediately before sorting, pass the cell suspension through a 40 μm filter, and wash through with an equal volume of ice-cold HBSS. Add 2 μl of DAPI stock solution, to exclude dead cells during sorting.

9) Isolate germ cells by FACS. We use an 85 μm nozzle, and the gating strategy described below. In our experience, approximately 15–20 min of sorting time is required for each pair of testes.

2.3.3. Gating for germ cell subpopulations

Fig. 5 shows our standard gating strategy, which gives high purity for meiotic and late mitotic cell populations, from type B spermatogonia through early pachytene spermatocytes. Specifically, Fig. 5 shows the gating results from a sort designed to enrich for leptotene spermatocytes. The input to this sort was a pair of synchronized testes, collected 8 d after RA restoration, and verified by staging to contain leptotene spermatocytes.

We first gate based on light scatter (forward and side scatter area), which largely assays cell size (Shapiro, 2003) (Fig. 5A). The majority of cells in this sample are leptotene spermatocytes (Fig. 3D), which are homogeneous in light scatter and can be easily gated. Next, we gate for single cells, using light scatter (Shapiro, 2003), and we gate for live cells, using DAPI fluorescence (Fig. 5B and C). For DAPI detection, we use a 375 nm UV laser and a 450 nm/520 nm bandpass filter. After
these three gating steps, we are ready to sort a highly purified population of leptotene spermatocytes (Fig. 5F). We note that, because the target cell population is well separated from contaminating cells (Fig. 5A), we can use a fairly fast sorting rate without compromising sort efficiency: on the FACSARia II instrument, we use a flow rate of \( \sim 60 \mu l/\text{min}. \)

To achieve greater purity, we use transgenic mice that carry a fluorescent marker of germ cells (Fig. 6). With this Mvh-Cre/tdTomato germ cell lineage tracing system, all germ cells in the postnatal testis express some level of the fluorescent protein tdTomato under the control of the CAG promoter (Fig. 6A). In somatic cells, tdTomato protein is absent, due to the presence of a STOP codon that is excised in germ cells. While the CAG promoter is generally thought to confer ubiquitous expression (Madisen et al., 2010), we observed that

---

**Fig. 7. Gating for STRA8-positive preleptotene spermatocytes and for zygotene spermatocytes.** (A and D) We first gate for the STRA8-positive preleptotene (A) and zygotene (D) spermatocyte populations by cell size (black outlines). Red represents areas of highest density on the scatter plot. FSC-A: forward scatter-area; SSC-A: side scatter-area. Following the size gate, we gate for single cells and for live cells as in Fig. 5 B and C. (B and E) Next, we optionally gate for tdTomato intensity (black outlines) to isolate STRA8-positive preleptotene (B) and zygotene (E) spermatocytes. Only cells that pass the size, single-cell, and live-cell gates are included in the scatter plot. (C and F) Summary of the gates, and the percentage of cells that pass each gate.
tdTomato fluorescence intensity in fact decreases gradually over the course of germ cell development, being brightest in early spermatogonia and only slightly above background in mid/late pachytene spermatocytes (Fig. 6B). For detection of tdTomato fluorescence, we use a 488 nm blue laser and a 585 nm/642 nm bandpass filter. Fig. 5E shows three distinct levels of tdTomato fluorescence, reflecting the three major cell populations in the synchronized testis: somatic cells (negative), leptotene spermatocytes (moderate), and spermatogonia (high). Combining tdTomato fluorescence with our previous gating strategy (Fig. 5D), we obtain a more precisely defined population of leptotene spermatocytes (Fig. 5F and Table 1). We find that a nearly identical gating strategy can be used for other late mitotic and early meiotic cell populations: STRA8-positive preleptotene spermatocytes (Fig. 7A-C), and zygotene spermatocytes (Fig. 7D-F). The Mvh-Cre/tdTomato lineage tracing system is helpful but not necessary for sorting these populations—they can be isolated by light scattering properties. 

Fig. 8. Gating for undifferentiated spermatogonia. (A) We first gate for single cells (black outline). Red represents areas of highest density on the scatter plot. SSC-A: side scatter-area; SSC-W: side scatter-width. (B) We next gate for live (DAPI-negative) cells (blue). Only cells that pass the single-cell gate (A) are included in the histogram. (C) Finally, we gate for tdTomato intensity (black outline). Only cells that pass the single-cell and live-cell gates (A and B) are included in the scatter plot. (D) Summary of the gates, and the percentage of cells that pass each gate. (E) Light scatter (size) profile of putative undifferentiated spermatogonia. Only cells that pass the single-cell, live-cell, and tdTomato-intensity gates (A-C) are included in the scatter plot. Putative undifferentiated spermatogonia do not cluster tightly on the scatter plot, indicating a fairly wide range of sizes. We believe that this wide range of sizes is observed because the cell cycle of undifferentiated spermatogonia is not subject to synchronization (van Pelt et al., 1995). FSC-A: forward scatter-area; SSC-A: side scatter-area. (F) Light scatter profile of putative undifferentiated spermatogonia (gated for single cells, live cells, and tdTomato intensity, from (E), in red), overlaid on overall light scatter profile (all data, ungated, in gray). This shows that the size range of putative undifferentiated spermatogonia overlaps with that of somatic cells of the testis.
alone. In contrast, our experience indicates that the Mvh-Cre/tdTomato lineage tracing system is necessary for the sorting of undifferentiated spermatogonia (Fig. 8A-D) and is helpful for sorting early-differentiating spermatogonia, because spermatogonia are somewhat heterogeneous in size (Fig. 8E-F) and because, at such early time-points, somatic cells outnumber germ cells (Fig. 2A).

2.4. High purities obtained by synchronizing, staging, and sorting

We have used the 3S approach to isolate germ cell subpopulations ranging from undifferentiated spermatogonia to early pachytene spermatocytes. As a representative test of the method, we have isolated and performed detailed purity assessments for three types of spermatocytes that had previously proved difficult to separate: late (STRA8-positive) preleptotene, leptotene, and zygotene. These encompass meiotic initiation in preleptotene, followed by key events of meiotic prophase: DNA double-strand break formation in leptotene, and break repair and homologous chromosome synopsis beginning in zygotene.

To enrich for these three phases of meiosis, we synchronize germ cell development and collect testes at 7, 8, and 10 d after RA restoration (Fig. 3 C, D, and E). We stage each sample, requiring that at least 90% of tubules contain the target cell population; we discard any samples that do not meet this criterion. We then sort and perform purity assessments on the sorted cells (Table 1). To assess purity, we immunostain fixed cells (for preleptotene samples) or meiotic chromosome spreads (for leptotene and zygotene samples). We distinguish preleptotene, leptotene, and zygote spermatocytes by staining for the meiotic initiation factor STRA8 and for the synaptonemal complex proteins SYCP3 (part of the lateral element) and SYCP1 (part of the axial element), using the criteria of Morelli et al. (2008) and Gaysinskaya et al. (2014). Representative immunostained cells and spreads are shown in Fig. 9.

We obtain high purity (~90%) for preleptotene, leptotene, and zygotene spermatocytes (Table 1), demonstrating that we can consistently separate these spermatocyte populations. When we compare these results to published data from unit gravity sedimentation and from DNA staining/FACS (Table 2) (Bellvé, 1993; Gaysinskaya et al., 2014), we find that, for many cell types, the purities obtained with 3S represent a substantial improvement over previous methods. In particular, 3S is able to separate leptotene and zygote spermatocytes with higher purity than was previously possible. Moreover, we are able to specifically isolate the subset of preleptotene spermatocytes that had initiated meiosis, as assessed by staining for the marker STRA8 (Fig. 9A). To our knowledge, this is the first time that STRA8-positive spermatocytes have been specifically isolated at high purity: the unperturbed testis contains a mixture of STRA8-positive and -negative preleptotene spermatocytes, which cannot be separated by unit gravity sedimentation or DNA staining/FACS. Separating STRA8-positive from STRA8-negative preleptotene spermatocytes should enable a better understanding of meiotic initiation and the earliest events of meiotic prophase.

We also calculated the purity of cells that could be obtained without the Mvh-Cre/ttdTomato lineage tracing system. As shown in Table 1, when we sort based on light scattering properties alone, we obtain purities of 75–88% for the three tested cell types, which is still higher than unit gravity sedimentation and is comparable to DNA staining/FACS. We are still able to separate STRA8-positive from STRA8-negative preleptotene spermatocytes without use of Mvh-Cre/ttdTomato. When sorting based on light scatter properties alone, purities may vary by germ cell type; to improve purity, one could combine 3S with DNA staining (Gaysinskaya et al., 2014) or with immunostaining for marker genes (see for example (Phillips et al., 2010)). In addition, it is always possible to use synchronization and staging without sorting (“2S”) (Figs. 3 and 4). We note that 2S represents an improvement over the commonly used “first wave of spermatogenesis,” which attempts to enrich for particular cell populations by timed collection of unsynchronized pubertal testes (Nebel et al., 1961).

Based on these findings, we believe that 3S can be used to isolate a wide range of mitotic and meiotic germ cell populations, at high purity. We have demonstrated that synchronization is maintained throughout both mitotic and meiotic germ cell development; throughout these processes, germ cell development is synchronized within a 24 h window. We have also found that 3S produces consistent purities of ~90% for the three tested steps of germ cell development. Thus, we expect that 3S can be used to isolate, at approximately 90% purity, any step of development that lasts for 24 h or more, from the undifferentiated spermatogonia until the loss of tdtTomato fluorescence in early/mid pachytene (Table 2). Thus, 3S should be able to separate the different populations of spermatogonia—undifferentiated, A1, A2, A3, A4, Intermediate, and B—in addition to different populations of spermatocytes—preleptotene, leptotene, zygote, and early and mid pachytene.

3. Discussion

For many mitotic and early meiotic cell types, our 3S approach yields higher purity and finer-grained separation of germ cell subpopulations than was achievable with the previous state-of-the-art methods (Table 2). In the mitotic phase, 3S should enable, for the first time, systematic separation of the steps of spermatogonial development. We anticipate that this will lead to better understanding of spermatogonial self-renewal, proliferation, and preparation for meiosis. In the meiotic phase, 3S yields improved purity of preleptotene, leptotene, and zygote spermatocytes; enables specific isolation of preleptotene spermatocytes that are positive for the meiotic initiation marker STRA8; and allows separation of multiple subpopulations of pachytene spermatocytes. This fine-grained separation of meiotic cell populations should improve understanding of the molecular events of meiotic initiation and early prophase—fundamental processes that occur in organisms from yeast to man.

In addition to providing precise germ cell populations at higher purity, the 3S protocol has several practical advantages. First, one uses the same basic protocol to sort many different cell populations, from undifferentiated spermatogonia to mid-meiotic prophase. To obtain different cell populations, one simply changes the amount of time that germ cells are allowed to develop after RA restoration. Reflecting this consistency, the purities obtained for preleptotene, leptotene, and zygote spermatocytes are quite similar.

Second, cells are treated gently in 3S. Because synchronization is achieved in vivo, the testis is subjected to minimal handling after dissection. It does not need to be stained with cytotoxic dyes (Durand and Olive, 1982), and sorting can be conducted quickly. Thus, most cells are alive at the time of sorting (Figs. 5C and 8B).

Finally, 3S gives high yields. For the isolation of spermatocytes, we obtained ~500,000 cells from each pair of testes (Fig. 9). This high yield is largely due to synchronization. In the unperturbed adult testis, the percentage of germ cells in any given phase of meiosis is low (Gaysinskaya et al., 2014); synchronization increases this percentage by a factor of 10 or more (Russell et al., 1990), allowing rapid sorting. The yield from a single animal, or in some cases several pooled animals, is sufficient for deep transcriptional profiling, as well as for genome-wide assays of epigenetic marks and transcription factor binding, and for other biochemical assays.

In the future, we anticipate that 3S can be extended to allow isolation of late meiotic and post-meiotic populations (round and elongating spermatids). Synchronization is maintained throughout post-meiotic spermatid development (Hogarth et al., 2013), so the main obstacle is identifying sorting methods suitable to these populations. Since tdtTomato fluorescence intensity diminishes over the course of germ cell development, our Mvh-Cre/ttdTomato lineage tracing system cannot be used to sort germ cells after mid-pachytene of meiosis, and by mid-pachytene the cellular composition of the testis
has become too complex to sort by light scattering properties alone (Fig. 3F). However, a variety of alternative sorting methods are available to isolate late meiotic and post-meiotic cell populations. The simplest is combining synchronization and staging with a DNA staining/FACS approach. DNA staining excels at separating germ cells by ploidy, so it is a natural approach for isolating haploid spermatids, and can be used to isolate 4 C spermatocytes as well (Gaysinskaya et al., 2014). Synchronization and staging could also be combined with unit gravity sedimentation or centrifugal elutriation—these sedimentation-based techniques are the current state-of-the-art for isolating late meiotic and post-meiotic germ cells, and would thus allow isolation of precise developmental windows of late meiotic germ cells. Combining 3 S with other germ cell sorting methods will encourage greater attention to the testis as a subject of study.

We hope that 3 S will expand the germ cell sorting toolkit to enable investigators to pursue biological questions that were previously difficult or impossible to experimentally address. First, 3 S could enable better understanding of the changes that occur during the long mitotic phase of spermatogenesis. Over the course of these transit-amplifying divisions, spermatogonia gain competence for meiosis as they undergo transcriptional, post-transcriptional, and epigenetic changes (Chakraborty et al., 2014; Chappell et al., 2013; Godmann et al., 2007; Shirakawa et al., 2013). By isolating different spermatogonial types (A1 through B) along this developmental progression, one could begin to understand these changes at a molecular and biochemical level. Second, by enabling separation of STRA8-negative and -positive preleptotene spermatocytes, 3 S could reveal the molecular changes that occur immediately before and after meiotic initiation, leading to better understanding of the regulatory network governing meiotic initiation. Third, by enabling isolation of large numbers of preleptotene, leptotene, and zygote spermatocytes, 3 S opens the door to more detailed genome-wide and biochemical characterizations of these phases of meiosis. To date, the most detailed studies of progression through meiotic prophase have been conducted in yeast, in part due to the ease of synchronizing meiosis and sporulation; 3 S could enable a clearer understanding of how meiotic prophase differs between mammals and lower eukaryotes (Chu et al., 1998; Hayase et al., 2004; Hunter, 2003; Panizza et al., 2011; van Werven and Amon, 2011).

Fourth, 3 S will facilitate measurements of translation state and protein content at each stage of germ cell development, deepening our understanding of the complex post-transcriptional regulation that occurs during spermatogenesis (Bettegowda and Wilkinson, 2010; Chappell et al., 2013; Liu et al., 2007). Finally, over both the mitotic and meiotic phases, 3 S will aid in characterizing the epigenetic state of germ cells. DNA and histone methylation states are known to change during the course of spermatogenesis, but the precise dynamics and control of these changes are not understood. By using 3 S to epigenetically profile precise steps of germ cell development, one could determine how imprinting and other epigenetic marks associated with normal embryonic development are established and maintained in germ cells, and how the epigenetic state of germ cells correlates, transgenerationally, with the epigenetic state and phenotype of offspring (Arnaud, 2010; Lesch et al., 2013; Sasaki and Matsui, 2008).

More broadly, the mammalian testis offers a potentially powerful model for studying a wide variety of biological processes, including cell proliferation and lineage commitment (Oatley and Brinster, 2008), the cell cycle, cellular remodeling (Russell et al., 1990), and alternative splicing and polyadenylation (Liu et al., 2007; Soumillon et al., 2013). However, testis biology can be daunting for the non-expert, due to the complex cellular composition of the testis. 3 S provides a new means to reduce this complexity. We hope that 3 S will be applied by investigators across many subfields of modern biology and biochemistry, and will encourage greater attention to the testis as a subject of study.

4. Materials and methods

4.1. Mice

Three strains of mice were used: wild-type (C57BL/6NTac); tdTomato (with a loxP-STOP-loxP-tdTomato construct in the Rosa26 locus, strain B6.Cg-Gt(Rosa)26Sortm14(CAG-tdTomato)Hs/J from The Jackson Laboratory) (Madien et al., 2010); and Mvh-Cre (with a Cre-mOrange fusion protein, driven by the endogenous Mvh promoter) (Hu et al., 2013). To generate pups carrying the Mvh-Cre/tdTomato germ cell lineage tracing system, generally females homozygous for Mvh-Cre were crossed to males homozygous for tdTomato; however, in some cases animals heterozygous for Mvh-Cre or tdTomato were used for breeding. (Note that females homozygous for Mvh-Cre are fully fertile, while males homozygous for Mvh-Cre are sterile.) All animals were genotyped by PCR for Mvh-Cre and tdTomato before testis collection; genotyping for tdTomato was performed using the protocol provided by The Jackson Laboratory, and genotyping for Mvh-Cre was performed as previously described (Hu et al., 2013). All experiments involving mice were approved by the Committee on Animal Care at the Massachusetts Institute of Technology.
4.2. Immunostaining of testis sections

Bouin’s-fixed, paraaffin-embedded sections from synchronized testes were prepared as described in Results. Slides were dewaxed and rehydrated with a xylene and ethanol series. Antigen retrieval was performed by heating in a 10 mM sodium citrate buffer (pH 6.0). For STRA8 immunostaining, slides were blocked with 2.5% horse serum and 5% BSA for 90 min and incubated for 60 min at room temperature with primary antibody: 1:500 anti-STRA8 (Abcam ab49505, rabbit polyclonal). Detection was colorimetric; slides were washed, incubated with ImmPRESS anti-rabbit IgG detection reagent (Vector Laboratories) for 30 min, and developed using a DAB substrate kit (Vector Laboratories). Slides were then counterstained with Mayer’s hematoxylin, dehydrated, and mounted with Permount (Fisher Scientific). For SYCP3 and γH2AX immunostaining, slides were blocked with 2.5% donkey serum for 60 min and incubated overnight at 4°C with primary antibodies: 1:250 anti-SYCP3 (Santa Cruz Biotechnology sc-74569, mouse monoclonal) and 1:250 anti-γH2AX (Abcam ab11174, rabbit polyclonal). Detection was fluorescent. Slides were washed and incubated for 60 min with 1:200 secondary antibodies (Jackson ImmunoResearch): Cy5-conjugated anti-rabbit IgG and rhodamine red X-conjugated anti-mouse IgG. Slides were mounted using Vectashield with DAPI (Vector Laboratories) and sealed with nail polish.

4.3. Fixing and staining intact sorted cells

After sorting, cells were fixed for 15 min in 4% paraformaldehyde (PFA) and then washed twice in PBS. After fixation, cells were re-suspended in PBS and stored at 4°C. Staining was performed at room temperature. Cells were settled onto poly(L) lysine coated coverslips, permeabilized for 10 min by incubation in 0.25% Triton X-100, and blocked with 2.5% donkey serum and 1% BSA for 90 min. The coverslips were incubated for 60 min with primary antibodies: 1:500 anti-STRA8 and 1:100 anti-SYCP3 (see above). Coverslips were then washed with PBS and incubated for 60 min with 1:250 secondary antibodies (Jackson ImmunoResearch): Cy5-conjugated anti-rabbit IgG and FITC-conjugated anti-mouse IgG. Coverslips were mounted and sealed as above.

4.4. Making and immunostaining meiotic chromosome spreads

Meiotic spreads were made following the protocol of (Peters et al., 1997). Briefly, after sorting, cells were re-suspended in hypotonic

---

Table 2: Comparison of purities obtainable with 3S, unit gravity sedimentation, and DNA staining/FACS. Purities obtainable with unit gravity sedimentation and DNA staining/FACS are from (Bellvé, 1993) and (Gaysinskaya et al., 2014), respectively. For DNA staining/FACS, all cell populations were sorted from adult testes. For unit gravity sedimentation, some populations were sorted from juvenile testes. For 3S, percentages shown in gray represent estimated purities for populations that we have not yet tested. Bottom table indicates that 3S should be able to split Type-A spermatogonia into multiple subpopulations, which is not possible with the other two methods. Durations of each step of development are calculated based on (Ahmed and de Rooij, 2009; Oakberg, 1956).

* The preleptotene stage of germ cell development lasts for 40 h; preleptotene spermatocytes express STRA8 for the last 24.5 h of their development (Endo et al., 2015).

** Undifferentiated spermatogonia are present in all stages of spermatogenesis. In WIN18,446-treated pubertal testes, before RA restoration, undifferentiated spermatogonia are the only germ cells present. Round and elongating spermatids have low tdTomato fluorescence, only slightly above background, so they cannot be sorted with the Mvh-Cre/tdTomato germ cell lineage tracing system. Synchronization is maintained, so sorting by alternative methods should be possible.

---

Footnotes:
- The preleptotene stage of germ cell development lasts for 40 h; preleptotene spermatocytes express STRA8 for the last 24.5 h of their development (Endo et al., 2015).

in a thin layer of suspension was then pipetted onto glass slides, which had been coated with RMA, using the aowViz library. Immunostaining images were processed with Fiji, and R packages were used to perform data analysis.
